

# Interphase Engineering via Solvent Molecule Chemistry for Stable Lithium Metal Batteries

Jiahang Chen<sup>+</sup>, Huichao Lu<sup>+</sup>, Xirui Kong, Jian Liu, Jiqiong Liu, Jun Yang, Yanna Nuli, and Jiulin Wang\*

**Abstract:** Lithium metal battery has been regarded as promising next-generation battery system aiming for higher energy density. However, the lithium metal anode suffers severe side-reaction and dendrite issues. Its electrochemical performance is significantly dependent on the electrolyte components and solvation structure. Herein, a series of fluorinated ethers are synthesized with weak-solvation ability owing to the duple steric effect derived from the designed longer carbon chain and methine group. The electrolyte solvation structure rich in AGGs (97.96 %) enables remarkable CE of 99.71 % (25 °C) as well as high CE of 98.56 % even at −20 °C. Moreover, the lithium-sulfur battery exhibits excellent performance in a wide temperature range (−20 to 50 °C) ascribed to the modified interphase rich in LiF/LiO<sub>2</sub>. Furthermore, the pouch cell delivers superior energy density of 344.4 Wh kg<sup>−1</sup> and maintains 80 % capacity retention after 50 cycles. The novel solvent design via molecule chemistry provides alternative strategy to adjust solvation structure and thus favors high-energy density lithium metal batteries.

## 1. Introduction

The rapid development of lithium-ion batteries has gradually reached the theoretical energy density. Recently, lithium metal battery attracts intensive attention owing to the high theoretical capacity (3860 mAh g<sup>−1</sup>), the lowest redox potential (−3.04 V vs. standard hydrogen electrode) and low density of lithium.<sup>[1]</sup> However, lithium metal anode suffers severe side-reaction because of its high electrochemical

reactivity, which leads to fast battery failure and low Coulombic efficiency (CE). Moreover, the unordered Li<sup>+</sup> flux renders dendrite growth, which is easy to pierce separator and causes short circuit.<sup>[2]</sup>

Electrolyte plays a determined role in the performance of lithium metal anode since the electrolyte components will react with lithium to form solid electrolyte interphase (SEI). In common “1 M” dilute electrolyte, the Li<sup>+</sup> coordinates with solvents to form solvent-separated ion pairs (SSIPs), thus rendering solvent-derived SEI which mainly consists of organic components. The thick SEI with inferior Li<sup>+</sup> diffusion ability causes adverse side-reaction and dendrite growth.<sup>[3]</sup> Recently, high-concentration electrolytes (HCEs) were reported via simply increasing salt concentration.<sup>[4]</sup> The high salt/solvent molar ratio intelligently favors anions to enter solvation sheath to generate contact ion pairs (CIPs) and aggregates (AGGs), where anions can preferentially reduce into SEI rich in inorganic species. It enables dendrite-free cycling of lithium metal anode with high CE over 99.0 %. Furthermore, considering the high viscosity, cost and low ionic conductivity of HCEs, inert solvents, such as hydrofluoroethers (HFEs), are introduced as diluent which not only remain the solvation structure, but also decrease the viscosity of electrolyte.<sup>[5]</sup> However, the large proportion of HFEs also increases the electrolyte cost and density, which hinders its practical application.

Based on the deeper understanding on the relationship between solvent structure and solvent-Li<sup>+</sup> interaction, the concept of solvents with weak-solvation ability (WSA) was proposed, which can maintain similar solvation structure with HCEs even at moderate salt concentration.<sup>[6]</sup> Several constructed works have been reported to design “WSA” solvents via molecule chemistry based on 1,2-Dimethoxyethane (DME).<sup>[7]</sup> For example, Cui et al. proposed ethylene glycol diethyl ether (DEE) with longer carbon chain compared with DME, which reveals decreased solvation ability.<sup>[8]</sup> Furthermore, a family of fluorinated-DEE molecules were designed to render LiF-rich SEI.<sup>[9]</sup> Additionally, the introduction of methine proposed by Jang Wook Choi can also reduce the solvent-Li<sup>+</sup> interaction via steric effect.<sup>[10,11]</sup>

Inspired by above-mentioned works, herein we synthesized a series of fluorinated ethers with longer carbon chain and further introduced methine group to realize duple steric effect (Figure 1). The electrolyte at moderate salt concentration consists of 97.96 % AGGs and enables remarkable CE of 99.71 % as well as high CE of 98.56 % even at −20 °C ascribed to the LiF-rich SEI derived from FSI<sup>−</sup> anion and

Figure 1. The molecular structures of fluorinated ethers and the functional mechanism in this work.

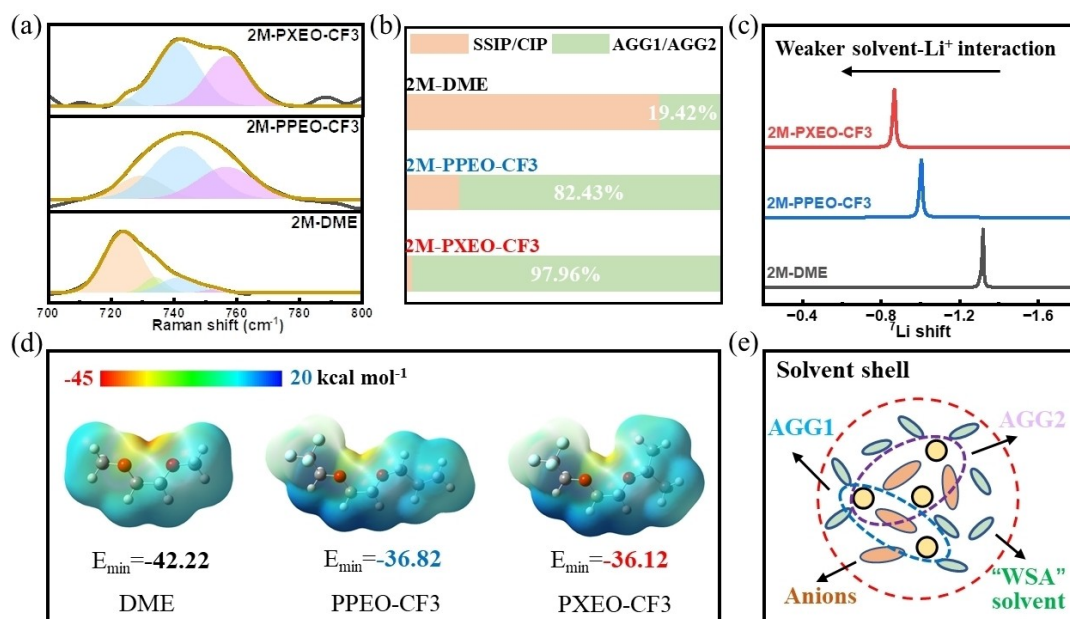

fluorinated solvent. Coupled with sulfurized pyrolyzed poly(acrylonitrile) (SPAN) cathode, the modified cathode interphase rich in LiF/LiO<sub>2</sub> favors superior performance in a wide temperature range (−20 to 50 °C). Moreover, the Li-SPAN pouch cell delivers benign energy density of 344.4 Wh kg<sup>−1</sup> and maintains 80 % capacity retention after 50 cycles.

## 2. Results and Discussion

The synthesis route of ethylene glycol (2,2,2-trifluoroethyl-n-propyl) ether (PPEO-CF<sub>3</sub>) and ethylene glycol (2,2,2-trifluoroethyl-i-propyl) ether (PXEO-CF<sub>3</sub>) is displayed in Figure S1 and analyzed via nuclear magnetic resonance (NMR) test as shown in Figure S2 and S3. The physico-chemical properties of different electrolytes are firstly compared as shown in Table S1. Compared with the low density of 2 M-DME electrolyte (1.08 g cm<sup>−3</sup>), both the fluorinated electrolytes maintain slightly higher density, of which the density of 2 M-PPEO-CF<sub>3</sub> is 1.15 g cm<sup>−3</sup> while the density of 2 M-PXEO-CF<sub>3</sub> is 1.13 g cm<sup>−3</sup>. Besides, the viscosity and ionic conductivity of different electrolyte are tested at 25 and 50 °C, respectively. The 2 M-DME electrolyte exhibits low viscosity of 3.30 mPa·s and remarkable ionic conductivity of 8.95 mS cm<sup>−1</sup> at 50 °C. The 2 M-PPEO-CF<sub>3</sub> electrolyte reveals increased viscosity whereas the 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits lower viscosity ascribed to the spatial effect of the isopropyl groups. Both the fluorinated electrolytes display relatively low ionic conductivity (>1 mS cm<sup>−1</sup>) because of the weak solvation ability of designed solvents and slow mobility of AGGs. It is worth noting that the 2 M-PXEO-CF<sub>3</sub> electrolyte maintains benign ionic conductivity (0.47 mS cm<sup>−1</sup>) even at −20 °C owing to the low viscosity and melting point of PXEO-CF<sub>3</sub>. Further-

more, the wetting ability on separator is compared via contact angle test as shown in Figure S4. Compared with the poor wetting ability of 2 M-DME (33.3°) and 2 M-PPEO-CF<sub>3</sub> (33.7°) electrolytes, the 2 M-PXEO-CF<sub>3</sub> electrolyte shows the lowest contact angle of 10.2° ascribed to superior affinity of isopropyl groups towards separator and can rapidly disperses throughout the separator.

The solvation structures of different electrolytes are further explored via Raman characterization. As shown in Figure 2a and S5, the 2 M-DME electrolyte reveals obvious peaks at 723 and 733 cm<sup>−1</sup> corresponding to free FSI<sup>−</sup> and coordinated FSI<sup>−</sup>, which indicates abundant SSIP and CIP.<sup>[12]</sup> In the 2 M-PPEO-CF<sub>3</sub> electrolyte, the proportion of SSIP/CIP declines while the proportion of AGG1/AGG2 remarkably increases to 82.43 %, whose characteristic peaks locate at 741 cm<sup>−1</sup> and 754 cm<sup>−1</sup>.<sup>[3]</sup> Moreover, it is worth noting that the 2 M-PXEO-CF<sub>3</sub> electrolyte maintains the highest proportion of AGG1/AGG2 up to 97.96 % ascribed to the prolonged carbon chain of 2 M-PXEO-CF<sub>3</sub> as well as the steric effect of its isopropyl groups (Figure 2b). Furthermore, the Fourier transform infrared spectroscopy (FTIR) test is also conducted as shown in Figure S6. In the 2 M-DME electrolyte, the peaks at 1364.4 cm<sup>−1</sup> and 1382.0 cm<sup>−1</sup> correspond to free FSI<sup>−</sup> and coordinated FSI<sup>−</sup>, respectively.<sup>[13]</sup> In contrast, higher content of coordinated FSI<sup>−</sup> exist in the proposed fluorinated electrolytes with weak solvation ability, which is coincident with the Raman results. Moreover, the proposed electrolytes consist of lower-content solvated solvents, which demonstrate the weak solvation ability of PPEO-CF<sub>3</sub> and PXEO-CF<sub>3</sub>. Additionally, the <sup>7</sup>Li NMR test can directly confirm the Li<sup>+</sup> coordination state with different solvents (Figure 2c).<sup>[8,14]</sup> The 2 M-PPEO-CF<sub>3</sub> electrolyte displays a down-field displacement (−1.00 ppm) compared with that of 2 M-DME (−1.32 ppm) while the 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits the most

**Figure 2.** (a) Raman characterization of different electrolytes. (b) Composition in solvation structure. (c) <sup>7</sup>Li NMR characterization of different electrolytes. (d) ESP of different solvents. (e) Solvation structure of electrolyte consisting of “WSA” solvent.

positive shift at  $-0.86$  ppm, indicating the weakest solvent- $\text{Li}^+$  interaction.

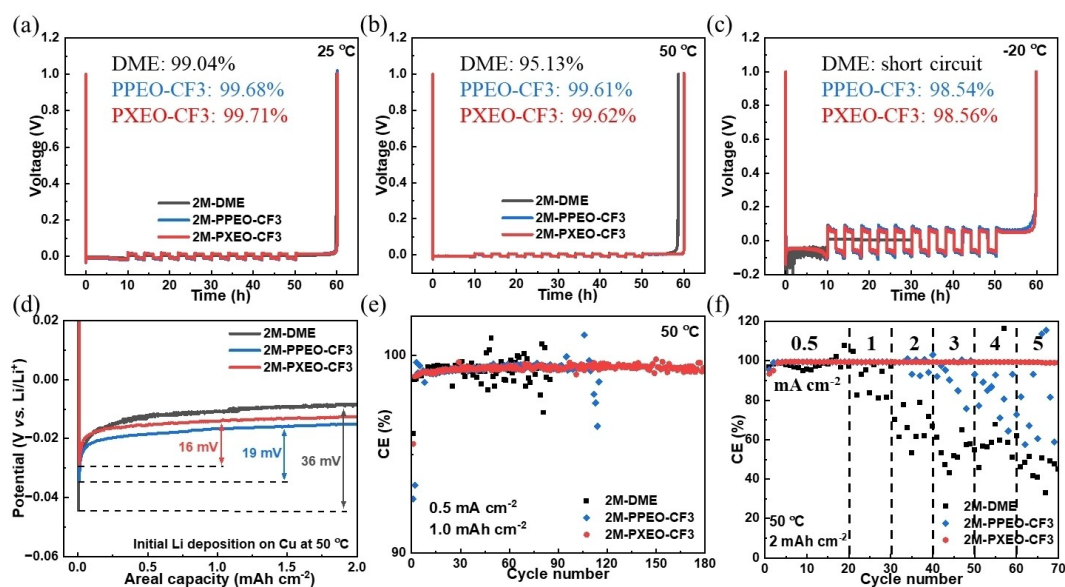

The solvation ability of different solvents is also compared via electrostatic potential (ESP) calculations, where the negative parts on the isopotential surfaces are easier to coordinate with  $\text{Li}^+$ .<sup>[15]</sup> As shown in Figure 2d, the value of  $E_{\min}$  of both PPEO-CF<sub>3</sub> ( $-36.82$  kcal mol<sup>-1</sup>) and PXEO-CF<sub>3</sub> ( $-36.12$  kcal mol<sup>-1</sup>) is higher than that of DME ( $-42.22$  kcal mol<sup>-1</sup>), which demonstrate the weak solvation ability of two fluorinated electrolytes. Thereby, we successfully tuned the unique solvation structure consisting of abundant AGG1/AGG2 via synthesizing fluorinated solvents with weak solvation ability. Moreover, compared with PPEO-CF<sub>3</sub>, the introduced methine group of PXEO-CF<sub>3</sub> not only further lowers the coordination ability of the neighboring oxygen atom, but also renders steric crowding around the first solvation shell, thus forming higher proportion of AGGs.

The average CE was calculated in a wide temperature range via previously reported protocol to evaluate the reversibility of lithium plating/stripping.<sup>[16]</sup> As shown in Figure 3a, the 2 M-DME electrolyte enables a benign CE of 99.04 % at 25 °C attributed to the increased salt concentration. In contrast, the CE increases to remarkable 99.68 % in the 2 M-PPEO-CF<sub>3</sub> electrolyte while the 2 M-PXEO-CF<sub>3</sub> electrolyte realizes a ultrahigh CE of 99.71 % ascribed to the unique solvation structure with AGG1/AGG2, revealing significant superiority compared with the reported works on “WSA” electrolyte (Table S2). Moreover, the proposed electrolytes maintain a high CE over 99.60 % even under elevated temperature of 50 °C, which is superior than that of 2 M-DME electrolyte (95.13 %), indicating prominently improved interfacial stability. In addition, the lithium behavior at extremely low temperature was also evaluated

using different electrolytes (Figure 3c). The 2 M DME electrolyte exhibits waving profile in initial discharge and then suffers short circuit. In contrast, both the proposed fluorinated electrolytes enable high CE over 98.5 % even at  $-20$  °C owing to moderate ionic conductivity and low melting point.

Besides, the electrochemical behavior at 50 °C was further investigated in detail. The Figure 3d displays the voltage-capacity curves of initial Li deposition on Cu substrate. Compared with the large nucleation and growth overpotential of 36 mV in 2 M-DME electrolyte, the 2 M-PPEO-CF<sub>3</sub> electrolyte enables lower overpotential of 19 mV while the 2 M-PXEO-CF<sub>3</sub> electrolyte realizes a remarkable 16 mV, demonstrating the fast interfacial ion diffusion with low barrier. The electrochemical impedance spectroscopy (EIS) results of Li-Cu also provide strong evidence as shown in Figure S7. The cells cycled in proposed electrolyte reveal extremely lower interfacial impedance ( $< 5$   $\Omega\text{cm}^{-2}$ ) than that in 2 M-DME electrolyte (nearly 30  $\Omega\text{cm}^{-2}$ ). The interfacial ion-transfer kinetics was also compared via measuring the exchange current density (Figure S8). Compared with the 2 M-DME electrolyte (0.137 mA cm<sup>-2</sup>), both the proposed electrolyte exhibits enhanced exchange current density of 0.202 mA cm<sup>-2</sup>, indicating the promoted interphase with promoted ion-transfer ability.

The long-term CE was also tested to evaluate the cycling stability of lithium metal anode (Figure 3e). The CE in 2 M-DME electrolyte becomes waving after 30 cycles whereas the 2 M-PPEO-CF<sub>3</sub> electrolyte prolongs the lifespan over 100 cycles. Moreover, the Li-Cu cell using 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits superior cycling stability with average CE of 99.40 % over 180 cycles. Furthermore, the rate performance was investigated as shown in Figure 3f. Under increased areal capacity (2 mAh cm<sup>-2</sup>), the CE in 2 M-DME

**Figure 3.** (a–c) The CE test of Li–Cu cells using different electrolytes at 25 °C (a), 50 °C (b) and –20 °C (c). (d) The voltage–capacity curves of initial Li deposition in different electrolytes. (e) The long-term CE using different electrolytes at 50 °C. (f) The CE test under different rates at 50 °C.

electrolyte rapidly declines to 95.0% even at low current density of  $0.5 \text{ mA cm}^{-2}$ . The 2 M-PPEO-CF<sub>3</sub> electrolyte could deliver benign CE of 99.4% under higher current density ( $1 \text{ mA cm}^{-2}$ ). In contrast, the 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits favorable endurance towards large current density, which ensures CE of 99.2% even under  $5 \text{ mA cm}^{-2}$ .

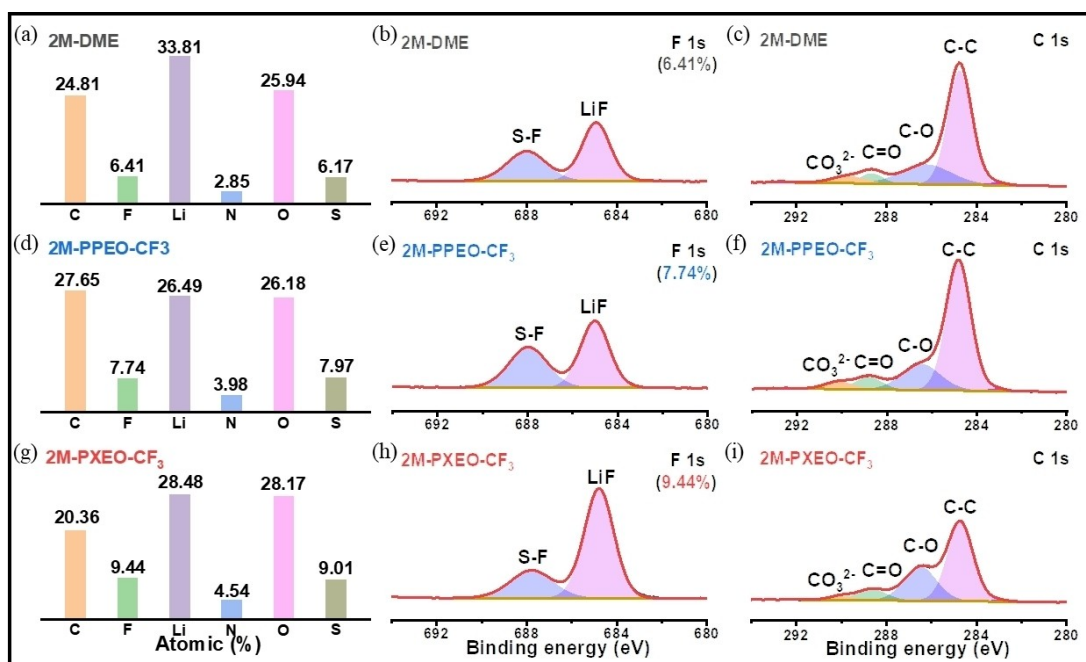

The lithium stability was also evaluated in Li–Li symmetric cells as shown in Figure S9. Under  $1 \text{ mA cm}^{-2}$ , the cell using 2 M-DME electrolyte suffers quick short circuit less in 400 h while the short circuit also occurs after 585 h cycling in 2 M-PPEO-CF<sub>3</sub> electrolyte. In contrast, the 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits excellent lithium stability over 800 h with low overpotential (30 mV). Thus, the cell using 2 M-PXEO-CF<sub>3</sub> electrolyte was further tested under higher current density (Figure S10). It delivers stable cycling with overpotential of 100 mV even under a harsh  $10 \text{ mA cm}^{-2}$ . The lithium morphology was observed via scanning electron microscopy (SEM) as shown in Figure S11. Severe dendrite growth and lithium pulverization could be observed after 200 h cycling in 2 M-DME electrolyte. In 2 M-PPEO-CF<sub>3</sub> electrolyte, it reveals micro-size rodlike deposition which can effectively decline the possibility of short circuit. Notably, the 2 M-PXEO-CF<sub>3</sub> electrolyte realizes large bulk deposition (nearly  $10 \mu\text{m}$ ) because the unique solvation structure successfully constructs stable interphase and then effectively hinders side-reaction.

The lithium interphase was analyzed by X-ray photoelectron spectroscopy (XPS). As shown in Figure 4, the interphase in 2 M-PXEO-CF<sub>3</sub> electrolyte consists of higher proportion of inorganic species derived from the unique solvation structure with AGG. In detail, both the S–F (688.0 eV) and LiF (684.8 eV) derives from the reduction of FSI<sup>–</sup> in 2 M-DME electrolyte.<sup>[17,18]</sup> In contrast, the proposed electrolytes enable higher F content because the fluorinated solvents may generate LiF. The N 1s and S 2p spectra (Figure S12)

also give strong evidence that 2 M-PXEO-CF<sub>3</sub> electrolyte is easier to construct anion-derived SEI than 2 M-DME electrolyte.<sup>[11,19]</sup> Besides, in the C 1s spectrum, 2 M-PXEO-CF<sub>3</sub> electrolyte renders higher proportion of C–O (286.2 eV) than C=O (288.6 eV) and  $\text{–CO}_3^{2-}$  (290.1 eV) species, indicating that the organic components in SEI mainly consist of polyether, which not only enables superior Li<sup>+</sup> diffusion ability, but also effectively prevents the side-reaction between lithium metal anode and electrolyte.<sup>[20]</sup> It is further proven in O 1s spectrum, where large peak (533 eV) corresponding to C–O–C can be observed.<sup>[21]</sup> Notably, compared with the 2 M PPEO-CF<sub>3</sub> electrolyte, the 2 M PXEO-CF<sub>3</sub> electrolyte enables richer inorganic species owing to the higher proportion of AGGs derived from the duple steric effect. Moreover, it also renders higher polyether content in the SEI since the  $\alpha$ -H in the methine of PXEO-CF<sub>3</sub> maintains higher reactivity than that in the methylene of PPEO-CF<sub>3</sub>, which may tend to rupture to form polyether according to our previous report.<sup>[22]</sup> The in-depth XPS was further conducted to highlight the superiority of 2 M PXEO-CF<sub>3</sub> electrolyte as shown in Figure S13. The F 1s spectrum indicates that the 2 M PXEO-CF<sub>3</sub> electrolyte enables richer LiF throughout the interphase compared with the 2 M PPEO-CF<sub>3</sub> electrolyte. It is worth noting that abundant R–OLi can be observed below the SEI surface instead of C–O–C and the Li<sub>2</sub>O peak gradually increases in the 2 M PXEO-CF<sub>3</sub> electrolyte, which maintains fast Li<sup>+</sup> diffusion ability. Additionally, the C 1s spectrum reveals that the proposed electrolytes render SEI consisting of polyether-rich outer layer and LiF-dominated inner layer, which accords with the results in O 1s spectrum.

Sulfur-based cathode was adopted to construct Li–S battery in this work owing to the high theoretical capacity and natural abundance of sulfur.<sup>[23]</sup> The electrochemical window of proposed electrolyte is enough for battery cycling

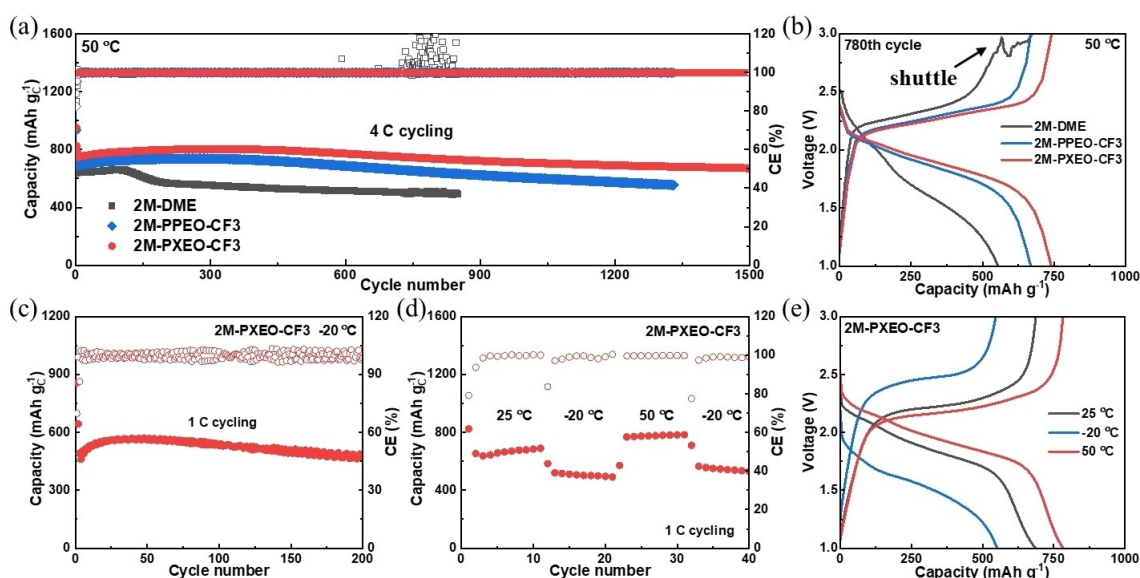

**Figure 4.** XPS characterization on lithium metal anode interphase in 2 M-DME (a–c), 2 M-PPEO-CF<sub>3</sub> (d–f) and 2 M-PXEO-CF<sub>3</sub> (g–i) electrolyte: (a, d, g) Molar ratio of different elements; (b, e, h) F 1s spectrum and (c, f, i) C 1s spectrum.

(Figure S14). However, the reported sulfur-based cathodes, no matter common sulfur@carbon composites or SPAN material, suffer shuttle effect in conventional ether-based electrolyte, leading to poor cycling stability and low capacity.<sup>[24]</sup> As shown in Figure 5a, the Li-SPAN battery using 2 M-DME electrolyte exhibits fast capacity loss (<500 mAh g<sup>−1</sup>, normalized in SPAN composite) after 120 cycles and typical shuttle occurs in 780 cycles (Figure 5b). In contrast, we intelligently designed the fluorinated

solvents with increased C/O molar ratio and weak solvation ability, thus lowering the solubility of lithium polysulfide. The 2 M-PPEO-CF<sub>3</sub> electrolyte enables high capacity of 737.3 mAh g<sup>−1</sup> and maintains 83.3 % capacity retention after 1200 cycles without shuttle effect. Moreover, the Li-SPAN battery using 2 M-PXEO-CF<sub>3</sub> electrolyte exhibits the best performance with remarkable capacity of 803.3 mAh g<sup>−1</sup>, corresponding to high sulfur utilization of 98.1 %. It delivers stable cycling over 1500 cycles with capacity retention of

**Figure 5.** (a, b) Long-term cycling stability of Li-SPAN batteries at 50 °C (a) and voltage-capacity profiles at 780<sup>th</sup> cycle using different electrolytes (b). (c) Cycling performance using 2 M-PXEO-CF<sub>3</sub> electrolyte at −20 °C. (d, e) Cycling performance at various temperature (d) and the voltage-capacity profiles (e).

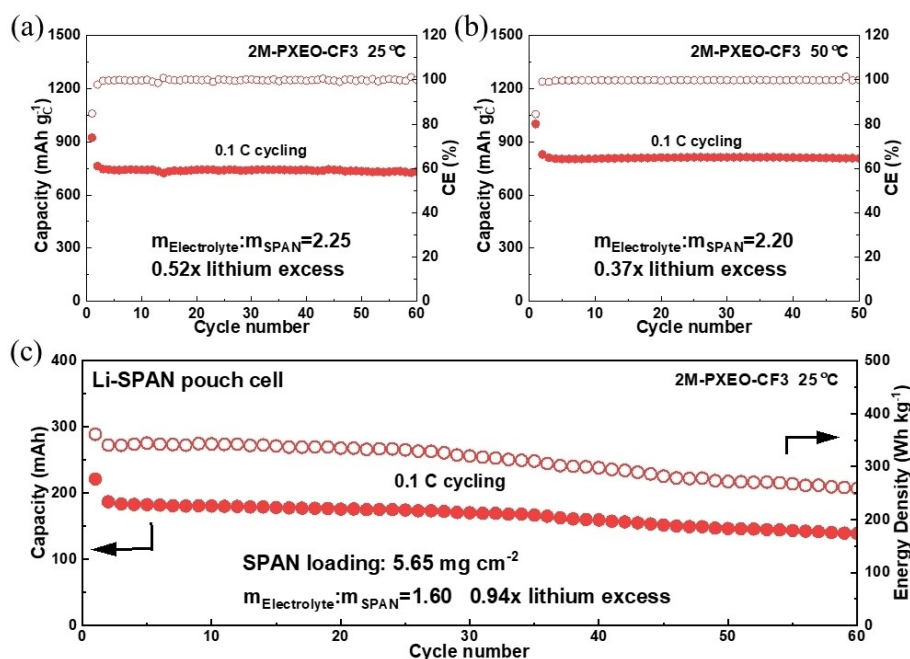

89.8 % and the lowest overpotential, which indicates effectively restrained shuttle effect and side-reaction even at elevated temperature. Furthermore, the polysulfide dissolving experiment was conducted to directly compare the solubleness in different solvents (Figure S15). After adding 1 M  $\text{Li}_2\text{S}_6$  in DME, the solution becomes dark brown quickly, indicating high polysulfide solubility in DME. In contrast, both the proposed fluorinated electrolytes exhibit low solubility towards polysulfide owing to the weak solvation ability, thus effectively hindering the shuttle effect. Additionally, a special procedure was designed which rest the cell at different discharged state for 48 h as shown in Figure S16. The totally recovered capacity indicates no self-discharge and excellent electrolyte stability ascribed to the solid-solid conversion mechanism without polysulfide shuttle.<sup>[25]</sup>

Moreover, ascribed to the superior compatibility with lithium under low temperature, the performance under  $-20^\circ\text{C}$  was further evaluated as shown in Figure 5c and S17. The battery using 2 M-DME electrolyte suffers rapid failure after 2 cycles while the 2 M-PPEO- $\text{CF}_3$  electrolyte exhibits significant cycling performance with slight capacity loss. In contrast, even with increased overpotential (Figure 5e), the Li-SPAN battery using 2 M-PXEO- $\text{CF}_3$  electrolyte still enables benign capacity of  $568.4 \text{ mAh g}_\text{C}^{-1}$  after activation and stable performance over 200 cycles, indicating excellent compatibility towards both lithium anode and SPAN cathode. Furthermore, the battery was cycled under wide temperature range from  $-20$  to  $50^\circ\text{C}$ , which performs stable cycling and quick capacity recovery (Figure 5d).

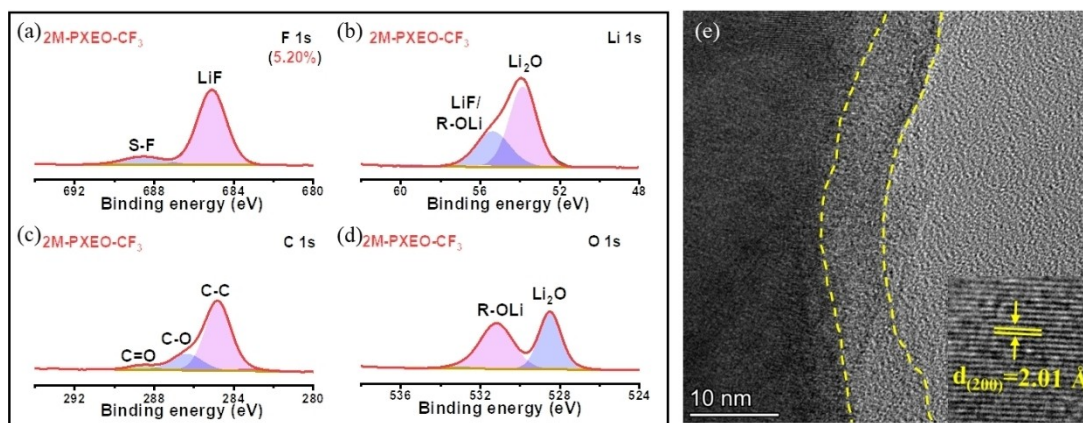

To explore the potential towards practical application, we simulated the cycling condition of limited lithium and

lean electrolyte. As shown in Figure 6a, even under 0.52x lithium excess and  $m_{\text{Electrolyte}}:m_{\text{SPAN}}=2.25$ , the Li-SPAN battery realizes high sulfur utilization of 92.8 % ( $763.5 \text{ mAh g}_\text{C}^{-1}$ ) and remains at  $732.3 \text{ mAh g}_\text{C}^{-1}$  after 60 cycles. The voltage-capacity curve indicates negligible polarization increases during cycling (Figure S18a). Besides, elevated temperature renders lower polarization and higher capacity. The battery at  $50^\circ\text{C}$  exhibits remarkable capacity of  $828.4 \text{ mAh g}_\text{C}^{-1}$  corresponding to sulfur utilization nearly 100 % under extremely low lithium excess (0.37) and electrolyte amount ( $m_{\text{Electrolyte}}:m_{\text{SPAN}}=2.20$ ). Even after 50 cycles, the sulfur utilization remains at 98 %.

Furthermore, Li-SPAN pouch cell was assembled and the key parameter was listed in Table S3. Considering the excellent wetting ability of electrolyte, the electrolyte amount ( $m_{\text{Electrolyte}}:m_{\text{SPAN}}$ ) was controlled in 1.60, which still accounts main proportion of 40.5 % (Figure S19). As shown in Figure 6c, the pouch cell reveals high capacity of  $769.0 \text{ mAh g}_\text{C}^{-1}$  and delivers energy density of  $344.4 \text{ Wh kg}^{-1}$  (based on cathode, anode, separator, electrolyte and current collector) after activation. It exhibits stable cycles over 50 cycles with benign capacity retention of 80 %, which shows great superiority compared with reported Li-S pouch cell listed in Table S4. However, it suffers slow but continued decline and remains 75 % capacity retention after 60 cycles. Although the side reaction occurred on both lithium anode and SPAN cathode has been greatly hindered via the electrolyte design and interphase engineering, it still exists and irreversibly consumes electrolyte as well as renders increased polarization. Thereby, the electrolyte systems require further exploration and more works including lithium metal anode protection and separate modifica-

**Figure 6.** (a) Cycling performance of Li-SPAN batteries using 2 M-PXEO- $\text{CF}_3$  electrolytes under 0.52x lithium excess and  $m_{\text{Electrolyte}}:m_{\text{SPAN}}=2.25$  at  $25^\circ\text{C}$ . (b) Cycling performance under 0.37x lithium excess and  $m_{\text{Electrolyte}}:m_{\text{SPAN}}=2.20$  at  $50^\circ\text{C}$ . (c) Cycling performance of pouch Li-SPAN batteries under 0.94x lithium excess and  $m_{\text{Electrolyte}}:m_{\text{SPAN}}=1.60$  at  $25^\circ\text{C}$ .

**Figure 7.** The XPS (a–d): F 1s spectrum (a); Li 1s spectrum (b); C 1s spectrum (c); O 1s spectrum (d) and TEM (e) analysis of SPAN cathode interphase cycled in the 2 M-PXEO- $\text{CF}_3$  electrolyte.

tion should be combined, which synergistically impel the practical application of Li–S battery.

The SPAN cathode interphase was also analyzed via XPS as shown in Figure 7. Rich LiF can be observed which mainly originates from the LiFSI salt owing to the solvation structure with abundant AGGs.<sup>[26]</sup> The C 1s spectrum reveals higher content of C–O than C=O species, indicating the formation of polyether, which may ascribe to the active  $\alpha$ -H in the methine of PXEO- $\text{CF}_3$  according to our previous work.<sup>[22]</sup> Moreover, the Li 1s spectrum displays two peaks at 53.9 and 55.4 eV respectively, corresponding to  $\text{Li}_2\text{O}$  and LiF/R-OLi.<sup>[18,27]</sup> The interphase rich in  $\text{Li}_2\text{O}$  is also demonstrated via O 1s spectrum. The organic C–C/R-OLi and inorganic  $\text{Li}_2\text{O}$  come from the PXEO- $\text{CF}_3$  solvent.<sup>[28]</sup> In addition, transmission electron microscope (TEM) is further conducted to investigate the SPAN interphase. The Figure 6e shows uniform and thin interphase (nearly 8 nm) coated on SPAN and clear lattice fringes with spacings of 2.01 Å corresponds to plane (200) of LiF.<sup>[29]</sup> The XPS and TEM results demonstrate that the 2 M-PPEO- $\text{CF}_3$  electrolyte contributes to cathode interphase rich in LiF and  $\text{Li}_2\text{O}$ , thus promoting fast reaction kinetics and suppress side-reaction.

### 3. Conclusions

In summary, we synthesize a series of fluorinated solvents with weak solvation ability via molecular design. The proposed electrolyte maintains unique solvation structure with high AGGs (97.96 %), thus constructing anion-derived interphase rich in LiF/ $\text{Li}_2\text{O}$ . The lithium metal anode exhibits ultrahigh CE of 97.1 % and excellent reversibility even at  $-20^\circ\text{C}$  with CE of 98.56 %. Moreover, the rationally designed solvents effectively address the shuttle issues in Li–S battery, enabling prolonged lifespan over 1500 cycles as well as superior performance under low temperature. The pouch cell using extremely low lithium and electrolyte delivers remarkable energy density of  $344.4 \text{ Wh kg}^{-1}$ . This

work sheds a light on novel solvent design and shows great potential towards practical Li–S battery.
